

Realization of Topological Quantum Computation with surface codes

Su-Peng Kou

Department of Physics, Beijing Normal University, Beijing 100875, China

In this paper, the degenerate ground states of Z_2 topological order on a plane with holes (the so-called surface codes) are used as the protected code subspace to build a topological quantum computer by tuning their quantum tunneling effect. Using a designer Hamiltonian - the Kitaev toric-code model as an example, we study quantum tunneling effects of the surface codes and obtain its effective theory. Finally, we show how to do topological quantum computation including the initialization, the unitary transformation and the measurement.

I. INTRODUCTION

Quantum computers are predicted to utilize quantum states to process tasks far faster than those of conventional classical computers. Various designs have been proposed to build a quantum computer, such as manipulating electrons in a quantum dot or phonon in ion traps, cavity QED, nuclear spin by NMR techniques. DiVincenzo pointed out that in order to build a real quantum computer[1], the following five criterions should be satisfied : 1) Scalability of extendible qubits; 2) Initialization (Creation of highly entangled states); 3) Local operations on multi-qubit; 4) Measurement of entangled states; 5) Long decoherence time. In particular, the fifth criteria (low decoherence condition) becomes a trouble to reach the goal.

Recently, people find that it may be possible to incorporate intrinsic fault tolerance into a quantum computer - topological quantum computation (TQC) which has the debilitating effects of decoherence and free from errors. The key point is to store and manipulate quantum information in a “non-local” way, namely, the “non-local” properties of a quantum system remain unchanged under local operations. An interesting idea to realize fault-tolerant quantum computation is anyon-braiding, proposed by Kitaev[2, 3]. He pointed out that the

degenerate ground states of a topological order make up a protected code subspace (the topological qubit) free from error[4, 5].

Topological order is a new type of quantum orders beyond Landau's symmetry breaking paradigm[6, 7, 8]. People know that there are two types of topological orders in two dimensional $S = 1/2$ spin models - non-Abelian topological ordered state and Z_2 topological ordered state. Those topological ordered states may appear in frustrated spin systems or dimer models[9, 10, 11]. Because of full gapped excitations, these topological orders are robust against any perturbations, even those perturbations that break all symmetries.

In non-Abelian topological orders, the elementary excitation are non-Abelian anyon with nontrivial statistics. Now people focus on realizing TQC by braiding non-Abelian anyons[3, 14]. The degenerate states undergoes a nontrivial unitary transformation when a non-Abelian anyon moves around the other. One can initial, manipulate and measure the degenerate ground states with several non-Abelian anyons[3, 14], which has become a hot issue recently [15, 16, 17, 18, 19, 20, 23, 24, 25, 26].

On the contrary, Z_2 topological order is the simplest topological ordered state with three types of quasi-particles: Z_2 charge, Z_2 vortex, and fermions[12]. Z_2 charge and Z_2 vortex are all bosons with mutual π statistics between them. The fermions can be regarded as bound states of a Z_2 charge and a Z_2 vortex. In the last decade, several exactly solvable spin models with Z_2 topological orders were found, such as the Kitaev toric-code model [2], the Wen's plaquette model [12, 13] and the Kitaev model on a honeycomb lattice [3]. In Ref.[26], an alternative way to design TQC is proposed by manipulating the toric codes - the protected code subspace of Z_2 topological orders. To manipulate the degenerate ground states we can tune tunneling by controlling external field on spin models. However, to build a real quantum computer, multi-qubit is necessary. It is indeed a challenge to realize a spin model on a manifold with higher genus in experiments. To solve this problem, in this paper we design TQC by manipulating the surface code (See detail in the main content) rather than toric code, since it is more easy to make a hole in a surface.

The paper is organized as follows. In Sec. II, we study the properties of the surface code. In Sec. III, an effective theory of the surface code in Z_2 topological orders is formalized. By using the Kitaev toric-code model as an example, we demonstrate how to control the surface code by tuning the tunneling of the degenerate ground states[4, 6, 7, 8]. In Sec. IV, based on the effective theory, the TQC is shown including the initialization, the unitary

FIG. 1: The scheme of the Kitaev toric-code model

transformation and the measurement. Finally, we draw the conclusions in Sec. V.

II. DEGENERATE GROUND STATES AS SURFACE CODES

In the paper, we demonstrate the TQC in Z_2 topological order by using a designed model - the Kitaev toric-code model (an effective model of the Kitaev model on two dimensional hexagonal lattice) as an example[2, 3, 4]. Here the Hamiltonian of the Kitaev toric-code model is described by [2]

$$H = -g \left(\sum_{i \in \text{even}} Z_i + \sum_{i \in \text{odd}} X_i \right). \quad (1)$$

where

$$Z_i = \sigma_i^z \sigma_{i+\hat{e}_x}^z \sigma_{i+\hat{e}_x+\hat{e}_y}^z \sigma_{i+\hat{e}_y}^z, \quad X_i = \sigma_i^x \sigma_{i+\hat{e}_x}^x \sigma_{i+\hat{e}_x+\hat{e}_y}^x \sigma_{i+\hat{e}_y}^x$$

with $g > 0$. $\sigma_i^{x,y,z}$ are Pauli matrices on sites i . See the scheme in Fig.1.

Firstly we study the ground state degeneracy $\mathcal{Q}$ of the Kitaev toric-code model. The ground state is a Z_2 topological state that is denoted by $Z_i = X_i \equiv +1$ at each site with energy,

$$E_0 = -g\mathcal{N} \quad (2)$$

where $\mathcal{N}$ is the total lattice number[4, 12, 13, 27]. Under the periodic boundary condition (on a torus), the degeneracy $\mathcal{Q}$ is dependent on $\mathcal{N}$: $\mathcal{Q} = 4$ on even-by-even ($e * e$) lattice, $\mathcal{Q} = 2$ on other cases (even-by-odd ($e * o$), odd-by-even ($o * e$) and odd-by-odd ($o * o$) lattices)[4, 12, 13, 27]. In addition, on a manifold with high genus ($\chi > 1$), $\mathcal{Q}$ becomes 4^χ on $e * e$ lattice and $4^\chi - 2$ on other cases. Kitaev have noted the degenerate ground states of the Kitaev toric-code model on a torus as *the toric code*. On the other hand, for the

FIG. 2: Mapping the qubit of a hole onto a pseudo-spin

ground states of the Kitaev toric-code model on a surface with open boundary condition, the ground state degeneracy now becomes

$$\mathcal{Q} = 2^n \quad (3)$$

(without considering the edge states)[28, 29]. Here n is the number of holes. In the following part we call the degenerate ground states of the Kitaev toric-code model on a surface with open boundary condition *the surface codes*.

To classify the degeneracy of the ground states (the surface codes), we define three types of closed string operators $W_c(\mathcal{C})$, $W_v(\mathcal{C})$ and $W_f(\mathcal{C}) = W_c(\mathcal{C})W_v(\mathcal{C})$. Here $W_c(\mathcal{C}) = \prod_{\mathcal{C}} \sigma_i^x$ (or $W_v(\mathcal{C}) = \prod_{\mathcal{C}} \sigma_i^z$) is the products of spin operators along a loop $\mathcal{C}$ connecting even-plaquettes (or odd-plaquettes) of neighboring links, with $\mathcal{C}$ denoting closed loops. It is obvious that the three types of closed string operators ($W_c(\mathcal{C})$, $W_v(\mathcal{C})$, $W_f(\mathcal{C})$) correspond to three quasi-particles (Z_2 charge, Z_2 vortex, and fermions) respectively. One can easily check the commutation relations between the closed string operators and the Hamiltonian

$$[H, W_c(\mathcal{C})] = [H, W_v(\mathcal{C})] = [H, W_f(\mathcal{C})] = 0. \quad (4)$$

In particular, for the surface codes, we can define two types of special closed string operators, $W_v(\mathcal{C}_A)$ and $W_f(\mathcal{C}_B)$. Here $\mathcal{C}_A$ denotes a closed loop around a hole (labeled by an index l) and $\mathcal{C}_B$ denotes a loop from the hole to the boundary of the system. Although $W_f(\mathcal{C}_B)$ is not the original closed string operator, its topological properties are the same. Due to the anti-commutation relation between $W_v(\mathcal{C}_A)$ and $W_f(\mathcal{C}_B)$,

$$\{W_v(\mathcal{C}_A), W_f(\mathcal{C}_B)\} = 0, \quad (5)$$

FIG. 3: Mapping the qubits of a line of holes onto a pseudo-spin chain

we may identify $W_v(\mathcal{C}_A)$ and $W_f(\mathcal{C}_B)$ as pseudo-spin ($S = \frac{1}{2}$) operators τ_l^z and τ_l^x , respectively. The ground states become the eigenstates of τ_l^z . Then one has two degenerate ground states (denoted by $|m_l\rangle$) for the case with a single hole. For $m_l = 0$, we have

$$\tau_l^z |m_l\rangle = |m_l\rangle, \quad (6)$$

and for $m_l = 1$ we have

$$\tau_l^z |m_l\rangle = -|m_l\rangle. \quad (7)$$

Physically, the topological degeneracy arises from presence or the absence of π flux of Z_2 vortex through the hole (See Fig.2). The values of m_l reflect the presence ($m_l = 1$) or the absence ($m_l = 0$) of the π flux in the hole.

Furthermore for the Z_2 topological order with n holes, the degenerate ground states have 2^n fold degeneracy as Eq.(3). The 2^n degenerate ground states can be mapped onto a 2^n -level quantum system of pseudo-spins $\hat{\tau}_l$ by the following correspondence,

$$|m_l = 0\rangle \rightarrow |\uparrow\rangle_l, \quad |m_l = 1\rangle \rightarrow |\downarrow\rangle_l.$$

We now get 2^n degenerate ground states of a chain of n holes. The 2^n degenerate ground states are denoted by

$$|m_1, \dots, m_l, \dots, m_n\rangle = |m_1\rangle \otimes \dots \otimes |m_l\rangle \dots \otimes |m_n\rangle,$$

where the two degenerate ground states of each hole are denoted by $|m_l\rangle$, $m_l = 0, 1$. In the following parts we use the degenerate ground states on a surface with a chain of holes to do TQC (See Fig.3).

III. PERTURBATIVE APPROACH OF QUASI-PARTICLES

In this section we study the properties of the quasi-particles. In this solvable model, Z_2 vortex is defined as $Z_i = -1$ at even sub-plaquette and Z_2 charge is $X_i = -1$ at odd sub-plaquette. The mass gap of Z_2 charge and Z_2 vortex is $2g$. In particular, the bound states of a Z_2 charge and a Z_2 vortex on two neighbor plaquettes obey fermionic statistic. All quasi-particles in this model have flat bands. The energy spectra are $E_v = E_c = 2g$ for Z_2 vortex and Z_2 charge, $E_f = 4g$ for fermions, respectively. In other words, the quasi-particles cannot move at all.

Under the perturbation

$$\hat{H}' = \sum_i \mathbf{h} \cdot \sigma_i = h^x \sum_i \sigma_i^x + h^y \sum_i \sigma_i^y + h^z \sum_i \sigma_i^z, \quad (8)$$

the quasi-particles begin to hop. The term $h^x \sum_i \sigma_i^x$ drives the Z_2 vortex without affecting fermion and Z_2 charge. For a Z_2 vortex at i plaquette $X_i = -1$, when σ_i^x acts on $i + \hat{e}_x$ site, it hops to $i + \hat{e}_x - \hat{e}_y$ plaquette denoted by $X_{i+\hat{e}_x-\hat{e}_y} = -1$,

$$X_i = +1 \rightarrow X_i = -1, X_{i+\hat{e}_x-\hat{e}_y} = +1 \rightarrow X_{i+\hat{e}_x-\hat{e}_y} = -1.$$

Moreover, a pair of Z_2 vortices at i and $i + \hat{e}_x - \hat{e}_y$ plaquettes can be created by the operation of σ_i^x ,

$$X_i = +1 \rightarrow X_i = -1, X_{i+\hat{e}_x-\hat{e}_y} = +1 \rightarrow X_{i+\hat{e}_x-\hat{e}_y} = -1.$$

Similarly, the term $h^z \sum_i \sigma_i^z$ drives the Z_2 charge without affecting fermion and Z_2 vortex. In particular, there exist two types of fermions : the fermions on the vertical links and the fermions on the parallel links. The term $h^y \sum_i \sigma_i^y$ drives fermions hopping without affecting Z_2 vortex and Z_2 charge : the fermions on the vertical links move vertically and the fermions on the parallel links move parallelly. That means both types of fermions cannot turn round any more.

To describe the dynamics of the quasi-particles we use the perturbative approach in Ref.[18, 19, 20, 21, 22, 26]. In the perturbative approach, the spin operators are represented

by hopping terms of quasi-particles,

$$\begin{aligned}
\sigma_i^x &\rightarrow (\phi_{1,i}^\dagger \phi_{1,i+e_x \pm e_y} + \phi_{1,i}^\dagger \phi_{1,i+e_x \pm e_y}^\dagger + h.c.), \\
\sigma_i^z &\rightarrow (\phi_{2,i}^\dagger \phi_{2,i+e_x \pm e_y} + \phi_{2,i}^\dagger \phi_{2,i+e_x \pm e_y}^\dagger + h.c.), \\
\sigma_i^y &\rightarrow (\phi_{3,i_3}^\dagger \phi_{3,i_3 \pm e_x} + \phi_{3,i_3}^\dagger \phi_{3,i_3 \pm e_x}^\dagger + h.c.) \\
&\quad + (\phi_{4,i_4}^\dagger \phi_{4,i_4 \pm e_y} + \phi_{4,i_4}^\dagger \phi_{4,i_4 \pm e_y}^\dagger + h.c.).
\end{aligned} \tag{9}$$

Here $\phi_{\alpha,i_\alpha}^\dagger$ ($\alpha = 1, 2$) are the generation operator of Z_2 vortex, Z_2 charge and $\phi_{\alpha,i_\alpha}^\dagger$ ($\alpha = 3, 4$) are the generation operator of fermions, respectively. i_1 denotes the position on even sub-plaquette and i_2 denotes the position on odd sub-plaquette. i_3 denotes the position on the vertical links and i_4 denotes the position on the parallel links. In addition, one should add a single occupation constraint (hard-core constraint) as

$$(\phi_{\alpha,i}^\dagger)^2 |\Psi\rangle = |\Psi\rangle \text{ or } \phi_{\alpha,i}^\dagger |\Psi\rangle = \phi_{\alpha,i} |\Psi\rangle \tag{10}$$

where $|\Psi\rangle$ denotes quantum state of the Kitaev toric-code model. Therefore, by the perturbation method, the Hamiltonian $\hat{H} = \hat{H}_0 + \hat{H}'$ can be represented by generation (or annihilation) operators of quasi-particles,

$$\begin{aligned}
\hat{H}_0 &\rightarrow 2g \sum_{i_1} \phi_{1,i_1}^\dagger \phi_{1,i_1} + 2g \sum_{i_2} \phi_{2,i_2}^\dagger \phi_{2,i_2} \\
&\quad + 4g \sum_{i_3} \phi_{3,i_3}^\dagger \phi_{3,i_3} + 4g \sum_{i_4} \phi_{4,i_4}^\dagger \phi_{4,i_4}
\end{aligned} \tag{11}$$

and

$$\begin{aligned}
\hat{H}' &\rightarrow -h^x \sum_{\langle i_1, j_1 \rangle} (\phi_{1,i_1}^\dagger \phi_{1,j_1} + \phi_{1,i_1}^\dagger \phi_{1,j_1}^\dagger) \\
&\quad - h^z \sum_{\langle i_1, j_1 \rangle} (\phi_{2,i_2}^\dagger \phi_{2,j_2} + \phi_{2,i_2}^\dagger \phi_{2,j_2}^\dagger) \\
&\quad - h^y \sum_{i_3} (\phi_{3,i_3}^\dagger \phi_{3,i_3 \pm e_x} + \phi_{3,i_3}^\dagger \phi_{3,i_3 \pm e_x}^\dagger) \\
&\quad - h^y \sum_{i_4} (\phi_{4,i_4}^\dagger \phi_{4,i_4 \pm e_y} + \phi_{4,i_4}^\dagger \phi_{4,i_4 \pm e_y}^\dagger) \\
&\quad - h^x h^z \sum_{\langle i_3, j_4 \rangle} (\phi_{3,i_3}^\dagger \phi_{4,j_4} + \phi_{3,i_3}^\dagger \phi_{4,j_4}^\dagger) + h.c..
\end{aligned} \tag{12}$$

In the following parts, we consider only the perturbation as $\hat{H}' = h^x \sum_i \sigma_i^x + h^y \sum_i \sigma_i^y$. The perturbative Hamiltonian of the quasi-particles becomes $\hat{H}_v + \hat{H}_c + \hat{H}_f$ where

$$\begin{aligned}
\hat{H}_v &= 2g \sum_{i_1} \phi_{1,i_1}^\dagger \phi_{1,i_1} - h^x \sum_{\langle i_1, j_1 \rangle} (\phi_{1,i_1}^\dagger \phi_{1,j_1} + \phi_{1,i_1}^\dagger \phi_{1,j_1}^\dagger) + h.c. \\
\hat{H}_c &= 2g \sum_{i_2} \phi_{2,i_2}^\dagger \phi_{2,i_2} \\
\hat{H}_f &= 4g \sum_{i_3} \phi_{3,i_3}^\dagger \phi_{3,i_3} + 4g \sum_{i_4} \phi_{4,i_4}^\dagger \phi_{4,i_4} - h^y \sum_{i_3} (\phi_{3,i_3}^\dagger \phi_{3,i_3 \pm e_x} + \phi_{3,i_3}^\dagger \phi_{3,i_3 \pm e_x}^\dagger) \\
&\quad - h^y \sum_{i_4} (\phi_{4,i_4}^\dagger \phi_{4,i_4 \pm e_y} + \phi_{4,i_4}^\dagger \phi_{4,i_4 \pm e_y}^\dagger) + h.c..
\end{aligned} \tag{13}$$

That means Z_2 charge cannot move any more.

For the perturbative Hamiltonian on $L_y \times L_x$ square lattice (L_y, L_x are all even integers), we obtain the dispersion of quasi-particles. The energy of Z_2 vortex is given by

$$\varepsilon_{k_1} = \sqrt{(\xi_{k_1} + 2g)^2 - \xi_{k_1}^2} \tag{14}$$

where

$$\xi_{k_1} = 2h^x [\cos(k_x + k_y) + \cos(k_x - k_y)]. \tag{15}$$

Here k_x and k_y are the wave vectors (The lattice constant has been set to be unit). The energy gaps of Z_2 vortex is obtained as $2g\sqrt{1 - \frac{4h^x}{g}}$. On the other hand, the energies of fermion is given by

$$\begin{aligned}
\varepsilon_{k_3} &= \sqrt{(\xi_{k_1} + 4g)^2 + 4(h^y \cos k_x)^2} \\
\varepsilon_{k_3} &= \sqrt{(\xi_{k_4} + 4g)^2 + 4(h^y \cos k_y)^2}
\end{aligned} \tag{16}$$

The energy gaps of fermion is obtained as $4g\sqrt{1 - \frac{2h^y}{g}}$. Thus one may manipulate the dispersion of Z_2 vortex and fermion by tuning the external field.

IV. EFFECTIVE PSEUDO-SPIN MODEL OF SURFACE CODES

It is known that the degenerate ground states of Z_2 topological orders have identically energy in thermodynamic limit. However, in a finite system, the degeneracy of the ground states is (partially) removed due to tunneling processes, of which a virtual quasi-particle moves around the holes before annihilated with the other[2, 4, 5]. In general cases, one will get very large energy gaps m_α ($\alpha = 1, 2, 3, 4$) for all quasi-particles and very tiny energy splitting of the degenerate ground states ΔE . That is $\Delta E \ll m_\alpha$. Based on this condition

FIG. 4: Tunneling process of Fermions from one hole to the boundary

FIG. 5: Tunneling process of Z_2 vortex moving around one hole

($\Delta E \ll m_\alpha$), we may ignore excited states with $E > m_\alpha$ and consider only the topological degenerate ground states. Thus we get a 2^n system as the effective pseudo-spin model of the surface code. In the followings, we will derive this model step by step.

In face, the closed string operators $W_v(\mathcal{C}_A)$ and $W_f(\mathcal{C}_B)$ can be considered as quantum tunneling processes of virtual quasi-particle moving along the loops. Let us take the quantum tunneling process of fermions as an example : at first a pair of the fermions is created. One fermion propagates around the hole driven by the operator σ_i^y and then annihilates with the other. Then a closed string of σ_i^y is left on the tunneling path behind the virtual fermion, that is just a closed string operator $W_f(\mathcal{C}_B)$. Such a process effectively adds the π flux to one hole and changes m_l by 1.

Firstly we calculate the the effective pseudo-spin model of single qubit (labeled by l -th hole) from tunneling processes. When a virtual fermion propagates from the boundary of the l -th hole to the boundary of the system, the quantum state $\begin{pmatrix} |\uparrow\rangle_l \\ |\downarrow\rangle_l \end{pmatrix}$ turns into

$$\begin{pmatrix} |\downarrow\rangle_l \\ |\uparrow\rangle_l \end{pmatrix} = \tau_l^x \begin{pmatrix} |\uparrow\rangle_l \\ |\downarrow\rangle_l \end{pmatrix}. \quad (17)$$

Such process is shown in Fig.4. By a degenerate perturbation approach[2, 4, 5, 30], one may obtain the energy splitting ΔE of the two ground states as

$$\delta E = \sum_j \langle \uparrow |_l \hat{H}' \left(\frac{1}{E_0 - \hat{H}_0} \hat{H}' \right)^j | \downarrow \rangle_l \quad (18)$$

which becomes

$$\delta E = 2 \frac{(h^y)^{\tilde{L}^y}}{(-8g)^{\tilde{L}^y-1}} \quad (19)$$

where $\tilde{L}^y$ is the length of the shortest path of a fermion from the boundary of the l -th hole to the boundary of the system. See detailed calculation in Ref.[30].

On the other hand, considering a virtual Z_2 vortex propagating around the hole (shown in Fig.5), the quantum states $\begin{pmatrix} |\uparrow\rangle_l \\ |\downarrow\rangle_l \end{pmatrix}$ turn into

$$\begin{pmatrix} |\uparrow\rangle_l \\ -|\downarrow\rangle_l \end{pmatrix} = \tau_l^z \begin{pmatrix} |\uparrow\rangle_l \\ |\downarrow\rangle_l \end{pmatrix}. \quad (20)$$

The corresponding energy difference ε of the two ground states is

$$\varepsilon = 2 \frac{(h^x)^{\tilde{L}^x}}{(-4g)^{\tilde{L}^x-1}} \quad (21)$$

where $\tilde{L}^x$ is the length of the shortest path of a Z_2 vortex around the hole.

Thus the dynamics of such a two-level quantum system (a single qubit) can be described by a simple effective pseudo-spin Hamiltonian

$$\begin{aligned} \mathcal{H}_{\text{eff}} &= \frac{\delta E}{2} (|\uparrow\rangle_l \langle \downarrow |_l + |\downarrow\rangle_l \langle \uparrow |_l) + \frac{\varepsilon}{2} (|\uparrow\rangle_l \langle \uparrow |_l - |\downarrow\rangle_l \langle \downarrow |_l) \\ &= \tilde{h}_l^x \tau_l^x + \tilde{h}_l^z \tau_l^z \end{aligned} \quad (22)$$

with $\tilde{h}_l^x = \frac{\delta E}{2}$ and $\tilde{h}_l^z = \frac{\varepsilon}{2}$.

Secondly we calculate the effective exchange interaction between two qubits. For simplicity, we consider only the perturbation as $\hat{H}' = h^x \sum_i \sigma_i^x + h^y \sum_i \sigma_i^y$. Then from Eq.(13), there exist two different tunneling processes : virtual fermion propagating from the boundary of l -th hole to the boundary of $(l+1)$ -th hole, virtual Z_2 vortex propagating around the two holes, respectively. See Fig.6 and Fig.7. Let us calculate the ground state energy splitting from degenerate perturbation approach.

When a virtual fermion propagating from the boundary of l -th hole to the boundary of $(l+1)$ -th hole, the quantum states turn into

FIG. 6: Tunneling process of fermions from one hole to another

FIG. 7: Tunneling process of Z_2 vortex moving around two holes

$$\begin{pmatrix} |\uparrow\rangle_l \\ |\downarrow\rangle_l \end{pmatrix} \otimes \begin{pmatrix} |\uparrow\rangle_{l+1} \\ |\downarrow\rangle_{l+1} \end{pmatrix} \rightarrow \begin{pmatrix} |\downarrow\rangle_l \\ |\uparrow\rangle_l \end{pmatrix} \otimes \begin{pmatrix} |\downarrow\rangle_{l+1} \\ |\uparrow\rangle_{l+1} \end{pmatrix} = \tau_l^x \otimes \tau_{l+1}^x \begin{pmatrix} |\uparrow\rangle_l \\ |\downarrow\rangle_l \end{pmatrix} \otimes \begin{pmatrix} |\uparrow\rangle_{l+1} \\ |\downarrow\rangle_{l+1} \end{pmatrix}.$$

Therefore, by the mapping, the pseudo-spin operator of the tunneling process of fermion corresponds to $\tau_l^x \otimes \tau_{l+1}^x$. See Fig.6. The energy splitting δE of the ground states is obtained as

$$\delta E = J_{l,l+1}^{xx} = \frac{(h^y)^{L_{yy}}}{(-8g)^{L_{yy}-1}} \quad (23)$$

where L_{yy} is the length of the shortest path from the boundary of l -th hole to the boundary of $(l+1)$ -th hole.

Similarly, when a virtual Z_2 -vortex propagates around l -th and $(l+1)$ -th holes, the quantum state turns into

$$\begin{pmatrix} |\uparrow\rangle_l \\ |\downarrow\rangle_l \end{pmatrix} \otimes \begin{pmatrix} |\uparrow\rangle_{l+1} \\ |\downarrow\rangle_{l+1} \end{pmatrix} \rightarrow \begin{pmatrix} |\uparrow\rangle_l \\ -|\downarrow\rangle_l \end{pmatrix} \otimes \begin{pmatrix} |\uparrow\rangle_{l+1} \\ -|\downarrow\rangle_{l+1} \end{pmatrix}.$$

The pseudo-spin operators of the tunneling process of Z_2 vortex correspond to $\tau_l^z \otimes \tau_{l+1}^z$. The

tunneling amplitude is

$$J_{l,l+1}^{zz} = \frac{(h^x)^{L_{xx}}}{(-4g)^{L_{xx}-1}} \quad (24)$$

where L_{xx} is the length of the shortest path round both l -th and $(l+1)$ -th holes. Thus under the perturbation $\hat{H}' = h^x \sum_i \sigma_i^x + h^y \sum_i \sigma_i^y$, the total effective Hamiltonian of the exchange interaction becomes

$$\mathcal{H}_{\text{eff}} \simeq \sum_l (J_{l,l+1}^{xx} \tau_l^x \tau_{l+1}^x + J_{l,l+1}^{zz} \tau_l^z \tau_{l+1}^z). \quad (25)$$

Finally, for a chain of n -hole, the degenerate ground states can be mapped onto a model of a n -pseudo-spin chain. By ignoring the next nearest neighbor coupling terms, the effective model of the Kitaev Toric-code model under the perturbation $\hat{H}' = h^x \sum_i \sigma_i^x + h^y \sum_i \sigma_i^y$ is naturally an anisotropy Heisenberg model

$$\mathcal{H}_{\text{eff}} \simeq \sum_l (J_{l,l+1}^{xx} \tau_l^x \tau_{l+1}^x + J_{l,l+1}^{zz} \tau_l^z \tau_{l+1}^z) + \sum_l (\tilde{h}_l^x \tau_l^x + \tilde{h}_l^z \tau_l^z). \quad (26)$$

The effective Hamiltonian in Eq.(26) indicates that the Kitaev Toric-code model is an example of so-called *topological order with controllable dispersion of quasi-particles*. For example, if one adds the external field along y -direction only encircling two holes, $\hat{H}' = h^y \sum_i \sigma_i^y$, the effective model is reduced into

$$\mathcal{H}_{\text{eff}} \simeq J_{1,2}^{xx} \tau_1^x \tau_2^x + \tilde{h}_1^x \tau_1^x + \tilde{h}_2^x \tau_2^x. \quad (27)$$

So one may adjust each parameters in the effective Hamiltonian by controlling the local distribution of the external field along special direction.

V. TOPOLOGICAL QUANTUM COMPUTATION WITH SURFACE CODES

To design a topological quantum computer, one needs to do arbitrary unitary operations on the surface codes. Then by adding the specific perturbations to the Kitaev Toric-code model, H' , one can change different quasi-particles' hopping and then manipulate the surface codes by controlling tunneling splitting of degenerate ground states. In this part we show the initialization, the unitary transformation and the measurement.

A. Initialization

Firstly we will show how to initialize the system into the quantum state $|\uparrow, \dots, \uparrow\rangle$. The basic idea is *to polarize all pseudo-spins by adding an effective field along x-direction and then removal it slowly*. This process will occur according to the Hamiltonian

$$H' = h^x(t) \sum_i \sigma_i^x \quad (28)$$

where $h^x(t) = h_0 e^{-t_0/t}$. At the beginning, there is a finite external field $h^x(t) \rightarrow h_0, t \rightarrow -\infty$. At the time $t = 0$, the external field disappears, $h^x(t) = 0$. From Eq.26, we get the effective pseudo-spin Hamiltonian of the surface codes

$$\mathcal{H}_{\text{eff}} \simeq \sum_l J_{l,l+1}^{zz} \tau_l^z \tau_{l+1}^z + \sum_l \tilde{h}_l^z(t) \tau_l^z \quad (29)$$

where $J_{l,l+1}^{zz} = \frac{[h^x(t)]^{L_{xx}}}{(-4g)^{L_{xx}-1}}$ and $\tilde{h}_l^z(t) = \frac{[h^x(t)]^{\tilde{L}^x}}{(-4g)^{\tilde{L}^x-1}}$. Here h_0 is positive and $\tilde{L}^x$ is an even number. Then if the system evolves *adiabatically and continuously* from high temperature to the ground state, after a long time, the final state can be a pure state of the topological order $|\uparrow, \dots, \uparrow\rangle$ which becomes the initial state prepared for TQC.

B. Unitary operations

Secondly we discuss how to do an arbitrary unitary transformation on the surface code[17, 18, 23]. The key point here is that *the unitary operations can be achieved by controlling the external field along particular direction within fixed times*.

A general pseudo-spin rotation operator of l -th qubit is defined by

$$U_l(\theta, \varphi, \gamma) = e^{-\frac{i}{\hbar} \gamma \tau_l^z} e^{-\frac{i}{\hbar} \varphi \tau_l^x} e^{-\frac{i}{\hbar} \theta \tau_l^z} \quad (30)$$

where $\gamma = \tilde{h}_l^z \Delta t_\gamma$, $\theta = \tilde{h}_l^z \Delta t_\theta$ and $\varphi = \tilde{h}_l^x \Delta t_\varphi$. One can use external field along different directions encircling only l -th hole to do TQC : firstly applying the external field along y-direction at an interval Δt_θ . The effective Hamiltonian becomes $\mathcal{H}_{\text{eff}} = \tilde{h}_l^z \tau_l^z$. Then, we swerve the external field along x-direction at an interval Δt_φ . The effective Hamiltonian becomes $\mathcal{H}_{\text{eff}} = \tilde{h}_l^x \tau_l^x$. Finally, the external field along y-direction is added at an interval Δt_γ . The effective Hamiltonian becomes $\mathcal{H}_{\text{eff}} = \tilde{h}_l^z \tau_l^z$.

Using such method, one can reach certain quantum operations demanded by TQC and have the ability to carry out gate operations onto the 'local' qubit (l -th hole) at will,

$$|\Psi\rangle_l = \alpha |\uparrow\rangle_l + \beta e^{i\phi} |\downarrow\rangle_l \quad (31)$$

with $\alpha, \beta \geq 0$ ($\alpha^2 + \beta^2 = 1$). An example is the $\frac{\pi}{8}$ gate of a local qubit (l -th hole), of which we have the general pseudo-spin rotation operator as

$$U_l(\gamma = \frac{\pi}{8}, \theta = 0, \varphi = \frac{\pi}{8}).$$

One can firstly applying a global external field along y -direction at an interval $\Delta t_\varphi = \frac{\pi}{8h_l^x}$. Then, we swerve the global external field along x -direction at an interval $\Delta t_\gamma = \frac{\pi}{8h_l^z}$. Similarly, one may design the global Hadamard gate as a special pseudo-spin rotation operator on each qubit,

$$U_l(\gamma = \frac{\pi}{4}, \theta = \frac{7\pi}{4}, \varphi = \frac{\pi}{4}).$$

Thus, in principle, people are capable of to do arbitrary unitary transformation on the protected subspace by controlling the external field on given regions (for example, a close loop around one or more hole).

C. Measurement

Thirdly we discuss the measurement of an arbitrary quantum states of the surface codes. The central point is *to measure the expected values of pseudo-spin operators by observing the quasi-particles' interferences from Aharonov-Bohm (AB) effect.*

To determine α, β and ϕ of quantum state of the l -hole, $|\Psi\rangle_l = \alpha |\uparrow\rangle_l + \beta e^{i\phi} |\downarrow\rangle_l$, we need to observe both fermion interference and Z_2 vortex interference. Fig.8 is a scheme to show the AB interference.

Firstly we detect the value of $\langle \tau_l^z \rangle = \langle \Psi | \tau_l^z | \Psi \rangle_l$ to determine α and β by AB effect from Z_2 vortex-interference. To observe the AB interference, we add a small external field, $h^x \rightarrow 0$ and $h^y = 0$. Now Z_2 vortex begin to hop. There exist symmetrical paths from both sides of the hole. For example, γ_1 and γ_2 shown in Fig.8 are two symmetrical paths. Then the symmetrical trajectories will contribute to the transition amplitude $T_{i,j}$ according to :

$$T_{i,j} = |\psi_{i,j}^{\gamma_1}|^2 + |\psi_{i,j}^{\gamma_2}|^2 + 2\epsilon |\psi_{i,j}^{\gamma_2} \psi_{i,j}^{\gamma_1}| \quad (32)$$

FIG. 8: The scheme of the interference around l -th hole.

where $\psi_{i,j}^{\gamma_2}$ and $\psi_{i,j}^{\gamma_1}$ are the wave functions of Z_2 vortex of the two trajectories. For the ground state $|\uparrow\rangle_l$, ϵ is unit. However, for the ground state with π -flux inside the hole $|\downarrow\rangle_l$, we have $\epsilon = -1$. Then we can distinguish these two cases. For two symmetrical paths $\psi_{i,j}^{\gamma_2} = \psi_{i,j}^{\gamma_1} = t_f$, we get a probability α^2 for $|\uparrow\rangle_l$ with $T_{i,j} = 4t_f^2$ and a probability β^2 for $|\downarrow\rangle_l$ with $T_{i,j} = 0$.

On the other hand, one can detect the value of $\langle \tau_l^x \rangle = \langle \Psi | \tau_l^x | \Psi \rangle_l$ to determine the parameter ϕ by observing fermion interference. To observe the AB interference of fermion, we add a small external field, $h^y \rightarrow 0$. The wave function of fermion has a periodic boundary condition from the hole to the boundary of the system for the ground state $|\uparrow'\rangle_l = \frac{1}{\sqrt{2}} |\uparrow\rangle_l + |\downarrow\rangle_l$ and an anti-periodic boundary condition for the ground state $|\downarrow'\rangle_l = \frac{1}{\sqrt{2}} |\uparrow\rangle_l - |\downarrow\rangle_l$. Then an arbitrary state $\alpha |\uparrow\rangle_l + \beta e^{i\phi} |\downarrow\rangle_l$ is re-written into

$$\sqrt{\frac{1}{2} + \alpha\beta \cos \phi} e^{i\phi'} |\uparrow'\rangle_l + \sqrt{\frac{1}{2} - \alpha\beta \cos \phi} \beta e^{i\phi''} |\downarrow'\rangle_l \quad (33)$$

where

$$\phi' = \arctan\left(\frac{\sin \phi}{\beta \cos \phi + \alpha}\right) \quad (34)$$

and

$$\phi'' = \arctan\left(\frac{\sin \phi}{\beta \cos \phi - \alpha}\right). \quad (35)$$

For two symmetrical paths (one from the hole, the other not), we get a probability $(\frac{1}{2} + \alpha\beta \cos \phi)$ for $|\uparrow'\rangle_l$ with $T_{i,j} = 4t_v^2$ and a probability $\frac{1}{2} - \alpha\beta \cos \phi$ for $|\downarrow'\rangle_l$ with $T_{i,j} = 0$. As a result, we determine the parameters α , β and ϕ of an arbitrary state $|\text{vac}\rangle = \alpha |\uparrow\rangle_l + \beta e^{i\phi} |\downarrow\rangle_l$.

The situation becomes more complex for 2-qubit. For 2-qubit with 2 holes (l -th and $l+1$ -th), a general entangled quantum state is given by

$$\begin{aligned} & \alpha_1 |\uparrow\rangle_{l+1} \otimes |\uparrow\rangle_l + \alpha_2 e^{i\phi_2} |\uparrow\rangle_{l+1} \otimes |\uparrow\rangle_l \\ & + \alpha_3 e^{i\phi_3} |\uparrow\rangle_{l+1} \otimes |\downarrow\rangle_l + \alpha_4 e^{i\phi_4} |\downarrow\rangle_{l+1} \otimes |\uparrow\rangle_l \end{aligned}$$

Fig9 (a)

Fig9 (b)

Fig9 (c)

FIG. 9: The scheme of the interference around l -th hole in (a), the interference around $l + 1$ -th hole in (b), and the interference around two holes in (c). Z_2 vortex cannot move in shadow region.

Here α_i and ϕ_i are all real number. Because of the constraint, $\sum_i \alpha_i^2 = 1$, there are totally $2(2^2 - 1) = 6$ independent parameters. One can detect the value of $\langle \tau_l^z \rangle$, $\langle \tau_{l+1}^z \rangle$, $\langle \tau_l^z \tau_{l+1}^z \rangle$ to determine α_i ($i = 1, 2, 3, 4$) from the AB effect of Z_2 -vortex-interference by $2^2 - 1 = 3$ times measurements. As shown in Fig.9, there are 3 cases of the Z_2 vortex-interference of different paths : γ_1^a and γ_2^a are two symmetrical paths around the hole l ; γ_1^b and γ_2^b are two symmetrical paths around the hole $l - 1$; γ_1^c and γ_2^c are two symmetrical paths around both hole l and hole $l - 1$. To do the observations, we only add a small external field in the regions without shadow, $h^x \rightarrow 0$ and $h^y = 0$ (In the shadow regions, there is no external field, $h^x = h^y = 0$). So the Z_2 -vortex is guided moving around given holes. Similarly, one

can detect the value of $\langle \tau_l^x \rangle$, $\langle \tau_{l+1}^x \rangle$, $\langle \tau_l^x \tau_{l+1}^x \rangle$ determine ϕ_i ($i = 2, 3, 4$) from the AB effect of fermion-interference by 3 times measurements.

For n -qubit with n holes, a general entangled quantum state is given by

$$\sum_i \alpha_i e^{i\phi_i} |\uparrow\rangle_i \otimes |\uparrow\rangle_l \otimes |\uparrow\rangle_{l+1} \quad (36)$$

Here α_i and ϕ_i are all real number. Because of the constraint, $\sum_i \alpha_i^2 = 1$, there are totally real $2(2^n - 1)$ independent parameters by changing the paths of quasi-particles. So people needs to do $2(2^n - 1)$ times measurement to determine the entangle state by changing different paths of AB interferences. One can determine α_i from $\frac{n(n+1)}{2}$ times measurements of Z_2 vortex-interference (to detect $\langle \tau_l^z \rangle$, $\langle \tau_l^z \tau_{l+1}^z \rangle$, $\langle \tau_l^z \tau_{l+1}^z \tau_{l+2}^z \rangle$, ..., $\langle \prod_l \tau_l^z \rangle$) and ϕ_i from $\frac{n(n+1)}{2}$ times measurements of fermion-interference (to detect $\langle \tau_l^x \rangle$, $\langle \tau_l^x \tau_{l+1}^x \rangle$), respectively. So one cannot determine all the parameters by the quasi-particles interferences if $n > 3$. It is still an unsolved problem to measure a general entangled quantum state of n -qubit with n ($n > 3$) holes.

D. Errors

Finally we discuss the errors and the constraint on our proposal.

Errors mainly come from the thermal effect. At finite temperature, Z_2 vortices are excited, their moving around the holes leads to errors, as causes "thermal hopping" from one degenerate ground state to another. The decoherence time t_{de} has been roughly estimated by the time to stretch a pair of Z_2 vortices over a distance equal to the average inter-particle separation (This is because the energy gap of Z_2 vortex is smaller than that of fermion). At low temperature, one can estimate that t_{de} is about $t_0 e^{\frac{4g}{k_B T}}$ where $t_0 = \frac{L_p}{v^*}$ is the time scale for Z_2 vortex moving the length of tunneling pathes, L_p [31]. v^* is the average speed of Z_2 vortex, which is estimated by $v^* \sim \sqrt{\frac{k_B T}{M_{eff}}}$ where $M_{eff} \simeq (2h^x)^{-1}$ is the effective mass of Z_2 vortex.

So there must exist a *crossover temperature* T^* from thermal hopping to quantum tunneling. Above T^* , the decay rate of the quantum states is determined by process of thermal activation, which is governed by the Arrhenius law,

$$t_0^{-1} e^{-\frac{4g}{k_B T}}. \quad (37)$$

FIG. 10: The crossover temperature for an example of tunneling process of Z_2 vortex. The scale of temperature is $\frac{k_B L_p}{4g}$

Therefore at high temperature the errors proliferate and one cannot get reliable TQC. Below T^* , quantum tunneling processes dominate, the rate of which goes as e^{-B} where B is about

$$B \sim \max(L_p \ln \frac{4g}{|h_x|}, L_p \ln \frac{8g}{|h_y|}). \quad (38)$$

Ignoring the prefactor and equating the exponents, one obtains

$$T^* = \frac{4g}{k_B B}. \quad (39)$$

Fig.10 shows the crossover temperature via h_x for a quantum tunneling process of Z_2 vortex. Thus if the temperature is kept far below T^* , $T \ll T^*$, one may do unitary operations safely.

However, because of the errors from the stochastic fields, we still get in trouble on storing quantum information by the surface codes. To store quantum information, all quantum tunneling processes need to be suppressed as low as possible, $e^{-B} \rightarrow 0$. That means the external fields should be removed, $h^x \equiv h^y \equiv 0$. Now the estimation of the crossover temperature in Eq.39 is invalid. Without external fields, due to the diverge effective masses of Z_2 vortex, $M_{\text{eff}} \rightarrow \infty$, one may store the quantum information for arbitrary long time, $t_{\text{de}} \rightarrow \infty$. Whereas, the stochastic noise fields leads to a finite decoherence time t_{de} . Thus to get a long-lived quantum information, both the temperature and the stochastic noise fields should be suppressed below a threshold. See detail in Ref.[32].

VI. SUMMARY

In this paper, we find an alternative way towards designing a quantum computer that may be possible to incorporate intrinsic fault tolerance. Using the Kitaev toric-code model as an example, we obtain the effective pseudo-spin model that can be mapped onto the anisotropic Heisenberg model of a pseudo-spin chain in external field. Then one may tune the parameters of the effective pseudo-spin model by controlling tunneling processes of the surface codes by applying external field along special direction on lattices. In particular, five criterions to build a quantum computer are satisfied :

1. Scalability of extendible qubits : The qubits is the so-called surface codes (two degenerate ground states of Z_2 topological orders on a plane with a hole). So the quantum computer is just a line of holes in the Z_2 topological order.
2. Initialization (Creation of highly entangled states) : We may polarize the pseudo-spins by adding an effective field along x-direction and then removing it slowly.
3. Local operations on multi-qubit : The unitary operations can do by controlling the external field along particular direction within fixed times.
4. Measurement of entangled states : We may measure the expected values of pseudo-spin operators by observing the quasi-particles' interferences from AB effect.
5. Low decoherence : Below the crossover temperature T^* , the decoherence processes will be controlled as low as possible.

Finally we discuss the realization of the Kitaev toric-code model. Because it can be regarded as an effective model of the Kitaev model on a two dimensional hexagonal lattice, one may realize the Kitaev model firstly. The realization of the Kitaev model has been proposed in an optical lattice of cold atoms in Ref.[33, 34] and in Josephson junction array of a superconductor in Ref.[35]. So it is possible to design a quantum computer in these system in the future.

In general, to design a topological quantum computer via quantum tunneling effect, there are four necessary conditions : 1) Z_2 topological order as the ground states; 2) controllable dispersion of quasi-particles; 3) space with nontrivial topological structure (manifold with

high genus or multi-hole); 4) low temperature and low noise. Thus considering these conditions, one may do TQC based on other models.
